Arrhythmias and ECG changes in life threatening hyperkalemia in older patients treated by potassium sparing drugs

Marie Berkova¹, Zdenek Berka², Eva Topinkova²

Background. Severe hyperkalemia is a life threatening condition that can cause fatal rhythm disturbance and terminal heart arrest. The most common cause of hyperkalemia in older patients is that of iatrogenic medication-related etiology due to associated polymorbidity, polypharmacy and reduced reserve metabolic capacity. The aim of this paper is to increase awareness in the clinicians of the risk of hyperkalemia in elderly patients treated by potassium sparing drugs.

Methods and Results. We present two case reports of hyperkalemia ≥ 9.0 mmol/L induced by potassium sparing medications with cardiac arrhythmias and severe ECG changes including atrial asystole, disturbance of intraventricular conduction and morphological changes such as tenting T waves and deformed wide QRS complexes. The most frequent causes of hyperkalemia in elderly patients are discussed and electrocardiogram changes and arrhythmias in hyperkalemia are analyzed, as well as their treatment and prevention.

Conclusion. Potassium sparing drug therapy in older persons requires more frequent monitoring especially when drugs or their doses are changed, or during concomitant acute illness.

Key words: hyperkalemia, electrocardiogram, potassium sparing drugs, elderly patients

INTRODUCTION

Potassium imbalance represents the most common electrolyte disturbance in older patients. Though hypokalemia is known to be associated with increased hospitalization and mortality in patients with cardiovascular and renal diseases¹,², severe hyperkalemia is a life threatening condition too³. It may be registered particularly in oligoanuric renal failure patients and other acute conditions (Table 1). However, more frequent use of angiotensin-converting enzyme inhibitors (ACEI), angiotensin II receptor antagonists and direct renin inhibitors, often combined with other potassium sparing drugs in the management of chronic cardiovascular diseases, contributed to increased incidence of clinically significant hyperkalemia in clinical practice, often in older patients⁴-¹². 75% of hyperkalemia cases in institutionalized patients are induced by potassium sparing drugs (Table 2). Hyperkalemia ≥ 6 mmol/L is observed in 0.8% of ACEI and 2.8% of angiotensin II receptor antagonist users⁴. The combination of potassium sparing drugs multiplies the risk of this adverse drug event. The mortality rates of patients with hyperkalemia over 7.0 mmol/L reach 67% if not promptly corrected¹⁴,¹⁵. Due to changes in pharmacokinetics and pharmacodynamics adverse drug reactions (ADR) are more common in older people. Age-related changes in drug absorption, body composition and drug distribution compartments, reduction of metabolic and elimination reserve capacities (renal and hepatic functions), chronic polymorbidity accompanied by polypharmacy are among factors contributing to increased risk of ADR (ref.¹⁶). In this article we present two recent case reports of severe hyperkalemia in older patients.

CASE REPORT 1

An 83-year-old Caucasian woman was referred to the Emergency Department of Internal Medicine for progressive worsening of generalized muscle weakness and bradycardia 40 beats/min. Administration of Atropin 0.5 mg

Table 1. The causes of hyperkalemia.

- Renal failure with reduced diuresis
- Severe acidosis (e.g. diabetic ketoacidosis)
- Hyperglycemia
- Drugs
- Dehydration
- Rhabdomyolysis, polytrauma, crush syndrome, severe burns
- Catabolic conditions
- Addison’s disease
- Hypoaldosteronism
- Repeated blood transfusion
- Tumor lysis syndrome (after cytostatic therapy)
- Rare tubular syndromes (Gordon syndrome)
- Hemolyzed blood sample (repeat sample)
- High platelet or white blood count (artificially raise potassium level)-repeat sample in Lithium heparin
i.v. was ineffective. The patient with the history of arterial hypertension, moderate mitral valve insufficiency, type 2 diabetes mellitus controlled by diet therapy, mild diabetestic and hypertensive nephropathy with proteinuria (with creatinine in the normal range) was hospitalized four years ago for paroxysmal atrial fibrillation with rapid ventricle response and acute heart failure. Since that time she was treated with digoxin 0.25 mg tbl. 1-0-0, diltiazem 60 mg tbl. 1-0-0, losartan 50 mg tbl. 1-0-0, spironolactone 25 mg tbl. 1-0-1, amiloride/hydrochlorothiazide 5/50 mg tbl. ½-0-0 and warfarin 3 mg tbl. 1-0-0. She did well until the last few days when fatigue and progressive muscle weakness appeared. She was unable to stand up, much less to walk, although she was self-sufficient till that time. In the last two days, diarrhoea appeared. Urination was normal and the urine was of normal colour and quantity. No other subjective problems were reported by the patient.

On physical examination: weight 75 kg, height 170cm, BMI 26 kg/m², supine blood pressure 160/90 mmHg, pulse 40 beats/minute. The patient was fully oriented but bradypsychic, unable either to stand up or to sit due to profound muscle weakness, without significant signs of skin dehydration but with gently stale mucous membranes and tongue. Neurological reflexes were preserved but of slow motion response and quiet systolic murmur (2/6) was heard above mitral valve. Otherwise physical findings were normal.

Electrocardiogram at admission showed no atrial electric activity, regular rescue ventricular rhythm with 180 ms wide abnormal QRS complexes, rate 40/min. Higher T wave were seen especially in limb leads II, III, aVF (Fig. 1). Laboratory examination at admission showed extreme potassium level 9.62 mmol/L that was confirmed by repeated examination (Table 3). The patient was admitted to the Intensive Care Unit (ICU), a central venous catheter inserted and after initial administration of 10 ml of calcium gluconicum 10% twice repeatedly, glucose/insulin and rehydration infusions were applied. For mild metabolic acidosis solution of sodium bicarbonate 4.2% 200 mL was administered. After sufficient hydration had been achieved, infusions with potassium wasting diuretics (furosemide) were administered. The treatment was fortified with peroral resin Calcium polystryrene sulfonate (Calcium resonium) 15 g orally four times per day. Consequently serum potassium level gradually decreased till the normal range was achieved (Fig. 2). With serum electrolyte improvement the ventricular rhythm was replaced at first with sinus bradycardia with borderline prolongation of PQ interval of 200 ms and narrow QRS complex 110 ms, followed by sinus rhythm with heart rate 70 beats/min converting occasionally to atrial fibrillation (Fig. 3). With normalization of serum potassium level the muscle weakness and diarrhoea subsided. On the sixth day the patient was discharged in clinically stable condition and independent. The drug regimen was modified

### Table 2. The most common drugs that may increase serum potassium level.

- Potassium substituents
- Potassium sparing diuretics (e.g. amiloride)
- Aldosterone antagonists – spironolactone, eplerenone
- Angiotensin-converting enzyme inhibitors (ACEI), angiotensin II antagonists, direct renin inhibitors
- Nonsteroidal anti-inflammatory drugs
- Heparin, low molecular weight heparins
- Cyclosporin A
- Crystallic Penicillin (potassium salt)

### Table 3. Biochemical results of the woman - patient, Case 1.

with reduction of diuretics including potassium sparing amiloride. On follow-ups her serum potassium was repeatedly within normal range. Bradycardia did not re-occur.

**CASE REPORT 2**

The 73-old male with type 2 diabetes on insulin therapy with the history of hypertension, myocardial infarction, coronary artery bypass grafting (CABG) some years ago and chronic first degree atrioventricular block was referred to a hospital admission for growing weakness particularly of lower extremities with inability to stand. The patient’s medication included chronic intensive insulinotherapy (rapid acting insulin human recombinant HMR 24-6-18-6-18-6-18-6 IU s. c. a day), acetylsalicylic acid 100 mg tbl. 0-1-0, ramipril 10 mg tbl. 1-0-0, spironolactone 100 mg tbl. 1-0-0, hydrochlorothiazide/amiloride 25/2.5

Fig. 5. ECG of the man at admission – hyperkalemia 9.0 mmol/L (case 2).
mg tbl. 1-0-0 and rosuvastatin 20 mg tbl. 0-0-1. On admission the patient (height 179 cm, weight 90 kg, BMI 28.0 kg/m²) was fully oriented but unable to stand or sit, supine blood pressure 150/90 mmHg, heart frequency of 73/min.

**On the electrocardiogram** the P waves were not differentiated and bizarre wide QRS complexes 73/minute were present (Fig. 5). The biochemistry revealed hyperglycemia (27.5 mmol/L), acidosis (pH 7.21, base excess -9.0 mmol/L) and mineral imbalance with hyperkalemia 9.0 mmol/L (Table 4). After urgent treatment at the Emergency Department (0.9% solution of sodium chloride 500ml, Humulin R 20 IU, sodium bicarbonate 4.2% solution 200ml, Calcium gluconicum 10% 20ml and Furosemide 20mg intravenously, Calcium resonium 30 g p.o.) in hemodynamically stable patient the short hemodialysis was carried out. The decompensated diabetes mellitus was controlled by adjusted dosage of rapid acting insulin. After the restoration of homeostasis (Fig. 2) the warning ECG changes disappeared and sinus rhythm with chronic first degree atrioventricular block and narrow QRS complexes was restored (Fig. 6).

**DISCUSSION AND ANALYSIS OF HYPERKALEMIA ETIOLOGY**

Potassium metabolism

Potassium is a vital ion and most potassium is intracellular (98%). The mechanism controlling the intra and extra cellular difference is the sodium-potassium pump (Na⁺/K⁺-ATPase) (ref. 17). The serum potassium concentration is consistently associated with changes in pH (ref. 18). The normal kidney function is important for maintenance of potassium balance. Potassium is mainly excreted in distal tubules (some potassium is also lost via the digestive tract and sweat).

An important role in the metabolism of potassium is played by the renin – angiotensin – aldosterone system. Aldosterone acts on mineralocorticoid receptors of the cells of the distal tubule and the collecting duct of the kidney nephron and activates the Na⁺/K⁺ pump. The result of this process is reabsorption of sodium and excretion of potassium ions. ACEI, angiotensin II receptor antagonists and direct renin inhibitors decrease secretion of aldosterone and can cause potassium retention.

The inhibition of vasodilating prostaglandine production by cyclooxygenase inhibitors especially in patients with chronic heart failure can significantly reduce renal perfusion, glomerular filtration and tubular potassium excretion followed by hyperkalemia.

Hyperkalemia and muscle and myocardial function

Hyperkalemia slows down neuromuscular conduction and particularly in combination with negative chronotropic drugs can cause heart arrest. While mild hyperkalemia (5.5-6.0 mmol/L) causes no ECG changes, in moderate hyperkalemia (6.1-7.0 mmol/L) the ECG changes may be discreet and non specific. The initial typical ECG changes in hyperkalemia are usually narrow and spiked T waves, shortening of QT interval and merging T reflecting acceleration of the terminal phase of ventricular repolarization. In severe hyperkalemia (serum potassium > 7.0 mmol/L), sinus bradycardia, widening and flattening of P waves, conduction disturbances with prolongation of PR interval, wider QRS complex, Tawar bundle branch blocks, atrioventricular blockades (blockade of sodium channels) and ectopic electric activity can by seen. Sporadically ST depression with T wave inversions or ST elevation which may mimic acute myocardial infarction have been described. The most severe hyperkalemia is represented by disappearance of P waves and sinus rhythm is replaced by emergency junction or ventricular rhythm with bizarre shape QRS. The terminal rhythm is ventricular fibrillation and heart arrest. A potassium level of about 10.0 mmol/L, but often much lower, is definitely incompatible with life.

Hyperkalemia – induced failure of not only atrial capture with preserved ventricular pacing in a patient with a dual-chamber (DDD) pacemaker but also failure of both the atrial and the ventricular pacemaker captures have been reported. The ECG changes are strong impetus for urgent treatment of hyperkalemia. The 12-lead ECG and vital function monitoring in severe hyperkalemia is mandatory.

In two case reports, we described excessive hyperkalemia with severe cardiac conduction disturbances. In the

![Fig. 6. ECG after the restoration of normokalemia in the man (case 2).](image-url)
first case potassium sparing drugs and mild dehydration were the causal factors of hyperkalemia. In the second case it was uncompensated diabetes mellitus further potentiated the effect of potassium sparing diuretics. Bradycardia in the first case might have been associated with negatively chronotropic effects of concomitant use of diltiazem and digoxin, though the serum digoxin level was within the normal therapeutic range. But it is known, that old people are more sensitive to digoxine due to smaller distribution volume, possible drug interactions, limited renal function and higher sensitivity of Na+/K+-ATPase for digoxin. For this reason, a lower therapeutic level of digoxin 0.6 – 1.2 nmol/L is recommended in older patients compared to young and middle aged groups.

The presented patients were of advanced age, which put them at a higher risk of electrolyte disturbances. The main risk factors for hyperkalemia in the elderly are: limited metabolic and excretion function reserves, changes in body composition and drug distribution compartments, decline of sensory and cognitive functions with limited ability to promptly and adequately respond to external changes, polymorbidity and polypharmacy, that involve drugs influencing potassium homeostasis (potassium sparing diuretics, ACEI, angiotensin II receptor antagonists, direct renin inhibitors, non steroid antiinflammatory drugs, corticosteroids, beta blockers, some antibiotics, long term treatment by heparin). In the Czech Republic, polypharmacy may play a significant role as the average number of drugs prescribed to Czech seniors is high: 4-6 drugs in community-living elderly and 5-8 drugs in institutional care. In both presented case reports, the cause of hyperkalemia was multifactorial.

Clinical symptoms of hyperkalemia differ in relation to serum potassium level. Mild hyperkalemia is mostly well tolerated, moderate hyperkalemia may be asymptomatic as well. However, with increasing hyperkalemia the symptoms appear. The most frequent are weakness, fatigue, diarrhoea and confusion. In hyperkalemia > 6.5 mmol/L hospital admission is warranted with monitoring of cardiac rhythm and urgent therapy.

In the referred older patients, severe changes in ECG were present that – if not treated – could have led to death. The rescue chamber rhythm is the ultimate rhythm often followed by heart arrest. Despite a heart beat of 40/min, the patient case 1 tolerated bradycardia very well without signs of heart failure and without the necessity for installing temporary pacemaker. Although in hyperkalemia the peaked T waves mostly in all leads are usually described, in the first case we saw the highest tenting T waves only in the limb leads II, III, aVF, whereas in the second case the highest T waves were recorded in the limb lead II and the chest leads V4-6. The microbiological examination did not reveal an infectious etiology of the diarrhoea in case 1 and it was found to be one of the signs of hyperkalemia. With restoration of homeostasis, the diarrhoea vanished too. Hyperkalemia can be accompanied by other gastrointestinal symptoms such as stomach ache and vomiting, that were not present in reported patients. However, both patients reported a typical symptom – severe muscle weakness.

Treatment of hyperkalemia

The treatment of the woman in the first case report started with glucose infusion with rapid acting insulin. The infusion application was necessary to achieve sufficient hydration and to permit administration of potassium wasting diuretics (furosemide). The usual dosage of furosemide is 40-120 mg intravenously, in patients with renal failure and substantial fluid retention the dose may be increased. The rapid acting insulin in 10% glucose solution (more concentrated glucose may be administered into the central vein system) does not eliminate potassium from the body but shifts it from the extracellular compartment into the cells. In the second case the therapy was initiated by rapid acting insulin without glucose but 0.9% sodium chloride solution as the patient suffered from decompensated diabetes mellitus with hyperglycemia (Table 6). American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care guidelines for the management of hyperkalemia in adults 2005 recommend in the case of hyperkalemia >7 mEq/L with toxic ECG changes the use of 5-10 mL of Calcium chloride 10% (Calcium gluconicum 10% contains 1/3 the elemental calcium of Calcium chloride) intravenously over 3-5 min to shift potassium into the cells and reduce the effects of potassium at the myocardial cell membrane (it lowers the risk of ventricular fibrillation) (ref.44). The patients were closely monitored and we also administrated 10% Calcium gluconicum 10 ml though the effect of this treatment is transient (approximately 30 min) and the patients’ cardiopulmonary conditions despite ECG changes and bradycardia were stable. However, in digoxin treated patients, treatment with i.v. calcium may increase the toxicity of digoxin.

Some studies have reported that beta adrenergic agonists can shift the potassium into the cells. Inhalation of 10 mg of nebulized salbutamol was reported to induce a short term (about one minute) increase of hyperkalemia 0.15 mEq/L followed in 3-5 min by a decline ranging from 0.4 to 1.5 mEq/l and lasting up to 2-4 h, after which the level steadily increases to the original plasma potassium value. However, up to one third of patients with hyperkalemia do not respond to this therapy. Apart from the transient effect of salbutamol, the dosage for the treatment of hyperkalemia is many times higher (4-8x) than that one for bronchial obstruction therapy. It may cause severe adverse effects (flush, tremor, anxiety, tachycardia, arrhythmias) and be hazardous particularly in patients with cardiovascular diseases and in the elderly. There have been no convincing clinical trials using beta adrenergic agonists in the management of severe hyperkalemia and some experts consider this treatment not to be evidence-based. However, some guidelines admit this therapy. We do not use beta adrenergic agonists for the treatment of hyperkalemia either.

Calcium polystyrene sulfonate was added to the therapy of our patients to remove potassium from the body. The resin exchanges calcium for potassium ions.
The treatment of severe bradycardia with heart failure may be the temporary pacing under the condition that the myocardium is capable to respond to the stimuli. Despite severe hyperkalemia there was no need for pacing in our patients. In patient 2 in addition to pharmacological treatment, hemodialysis was performed that could be like hemofiltration definite treatment if other options fail. Using hemodialysis was very effective with steeper decline in serum potassium levels. In patient 1, hemodialysis was not commenced as the patient was hemodynamically stable and rehydration enabled loop diuretics use (furosemide). However, in this patient serum potassium decrease was slower than in the patient treated with hemodialysis.

CONCLUSION

Severe hyperkalemia is a life threatening condition and is considered to be a common cause of sudden death. The incidence of hyperkalemia is increasing in the elderly given the large number of risk factors. Potassium sparing drugs play an important role in the development of hyperkalemia. ECG changes are warning signs in hyperkalemia that must be treated without delay. Prevention of hyperkalemia and its complications encompasses more frequent monitoring of serum potassium levels particularly in patients treated with potassium influencing drugs or when drug dosis is changed and in case of acute illness. Adequate hydration is important. The development of new drugs to treat and prevent hyperkalemia, e.g. new polymeric potassium binders may improve health outcomes for patients at risk.
